Nefrologia. Vol. XVI. No. 2. 1996 Average blood pressure, variability and reactivity. Effects of Clonidin J. Océn Pujadas and J. Mora Macié Fundacion Puigvert. Nephrology service. Hypertension section. Barcelona SUMMARY Goals: To investigate the relationship between blood pressure (PA), its variability (VPA) and reactivity (RPA), we have given 12 essential hypertensive clonidine to reduce the adrenerous activity of the CNS. Methods: We use non-invasive pa-monitoring for 24 hours, at rest, for the study of PA and VPA. The RPA was examined using isometric exercise (EI). We determine plasma catecholamines (CAp), ARP and aldosterone. The protocol was carried out before and after administration of clonidine. Results: CAp decreased with clonidine: NA, from 251 ± 106 to 145 ± 40. A, 49 ± 35 to 25 ± 17. DA, 73 ± 41 to 59 ± 38. The 24 h PA (mmHg) decreased from 159.73 ± 13/98.36 ± 6 to 145.34 ± 14/90.09 ± 6, p < 0.0009/p < 0.0003. FC (ppm), 65 ± 8 to 56 ± 8, p < 0.0009. No change was observed in 24 h (mmHg) of sistole or diastolic VPA: before clonidine, 12.33 ± 3/9.14 ± 4 and VFC (ppm), 6 ± 2. According to Clonidin, 12.72 ± 3/8.19 ± 1, VFC: 6 ± 2, NS. Clonidine did not prevent the increase of PA and CAp to IS (mmHg) for SBP, +43; PAD, +28 mmHg; FC, +26 ppm. According to Clonidin: PAS, +49 mmHg; PAD, +28 mmHg; FC, +23 ppm, NS. The same applies to CPs that rise after ISIS: NA, +49%; A, +122%, except DA, 4%. These increments remain after clonidine: NA, +67%; A, +160% and DA, +24%. The changes were not significant, except for da, p < 0.0001. SRAA activity with clonidine decreased: basal ARP, 1.2 ± 1.2; 0.2 ± 0.1 ng/ml/h, p < 0.01. Aldosterone from 0.3 ± 0.1 to 0.2 ± 0.1, nmol/L, p < 0.03. As a result, PA decreases, but the VPA does not vary. The increase of PA is and the increase of CP after ISIS continues. Conclusions: As a result of these results, it is suggested that PA, VPA and RPA work and are regulated by various mechanisms and are not controlled, with the exception of PA, due to decreasing adrenergeactivity. VPA and RPA to IS exceed baror receptor regulatory mechanisms. Clonidine does not reduce the three factors studied at the same time, but reduce the level of PA; VPA and RPA increases start with lower pressure, which can be clinically important. P a l a b r a s Key: Essential hypertension. Variability. Reactivity. S i s t e m a renin-angiotensin aldosterone. Adrenergic system. Clonidine. 24-hour PA monitoring. Received: 20-X-95. In the final version: 16-I-96. Suppose: 18-I-96. Correspondence: Dr. J. Océn Pujadas. Nephrology service. Hypertension section. Cartagena, 340. 08025 Barcelona. 146 MEAN AND CLONIDINE MEAN BLOOD PRESSURE. EFFECTS OF CLONIDINE SUMMARY Objective: To investigate the relationship of the blood presumpnation its variability (BPV) and reactivity (BPR), we gave to a group of 12 essential hypertensive clonidto to reduce adreneric activity from the CNS. Methods: 24-h BP and BPV were ensured with 24 h non-invasive blood imbossing record. BPR was investigated with isometric exercise (IE). We identified plasma catecholamines (PCA), plasma reninactivity (PRA) and plasma aldosterone. (PAL). The entire protocol was performed before and after clonidine treatment. Results: PCA decreased with clonidine: NE, from 251 ± 106 to 145 ± 40. E, from 49 ± 35 to 25 ± 17 and DA, from 73 ± 41 to 59 ± 38, pg/ml. 24 h BP (mmHg) and HR decrease also: from 159.73 ± 13/98.36 ± 6 to 145.34 ± 14/90.09 ± 6, p < 0.0009/p < 0.0003; HR (bpm) from 65 ± 8 to 56 ± 8, p < 0.0009. No change was observed in 24 h BPV (mmHg): SBPV/DBPV 12.33 ± 2/9.14 ± 4 vs. 12.72 ± 3/8.19 ± 1, NS. HR 6 ± 2 vs 6 ± 2, NS. Clonidine could not avoid the BP and PCA increase according to IE. SPB +43, DBP +28 mmHg; HR +26 bpm. After Clodine they were: SBP +49 mmHg; DBP +28 mmHg; HR +23 bpm, NS. Something similar happened with PCAS, which compared IE: NE, 49%; E, 122%, only DA reduced, 4%. T h o s e increments also persisted with clonidine: NE, 67%, E, 160% and DA, 24%. Compared to the pre-treatment values, only changes in DA were significant, p < 0.000001. RAAS activity was reduced by clonidine: PRA decreased from 1.2 ± 1.2 to 0.2 ± 0.1, ng/ml/h., p Average blood pressure or PAM, is an average blood pressure during the heart cycle, roughly equal to diastolic pressure plus a third of the difference between diastolic pressure and systolic pressure. It is an average that tells your doctor how your body processes oxygen-containing blood that reaches your tissues and organs. It is used to explain the average blood pressure in a person during a single heart cycle. If it is under a person, it can go into shock, but if it is high, it can also have complications. Most people are familiar with the term systolic blood pressure, but it is not a sufficient measure of blood infusion. Arteries are fibrous, muscle vessels that carry blood from the heart to other structures throughout the human body, so the average blood pressure can help determine the actual blood pressure in the arterial walls. Most hospital tensiometers automatically calculate average blood pressure, but in the intensive care unit it is often controlled by an arterial line inserted into a catheter in an artery. For medium blood pressure, median blood pressure in the high range could be an indication that the heart needs to work much harder than it should cause stress in the heart, leading to advanced heart disease, blood clots, heart attack or stroke. enlarge your heart muscles, become thicker and life-threatening. Be. rises quickly in a short time the organs can fail. Low MAP can also be fatal if it is not treated, as the organs do not get the blood they need and the patient can be put in shock and the organs can fail. It can be caused by sepsis, bleeding, stroke or some kind of trauma. Here are some situations where organ infusion could come into play and effects MAP:Septic ShockAneurysm Abdominal Disorders on the headSitutions Normal blood pressure valuesThe normal ranges of average blood pressure are between 70 and 110 mm Hg. At least 60 are needed to provide enough blood to nourish the coronary arteries, kidneys and brain. If it falls below 60 for a considerable time, the organs can be deprived of oxygen. How average blood pressure is calculatedThe mean blood pressure is defined as the average pressure in a patient's arteries during a heart cycle and is considered a better indicator of infusion to vital organs than systolic blood pressure. In the calculation, it can only be determined by invasive control, but can also be calculated with a formula and diastolic blood pressure. Cardiology specialists say that this is not the best way to calculate the PAM, because reading is not an accurate measure, since the ventricles spend only about a third of the time on the sylstole, which is the working phase of the cycle. To calculate the average blood pressure, double diastolic blood pressure and add the sum of systolic blood pressure. Then divide by 3. For example, if a patient's blood pressure is 83 mm Hg/50 mm Hg, his PAM would be 61 mm Hg. There are several clinical situations in which it is particularly important to monitor average blood pressure. In patients with sepsis, vasopressors are often assessed on the basis of PAM or patients with head trauma or stroke, treatment may depend on this value. It is this constant pressure that, with the same peripheral resistance, would produce the same flow rate (heart minute volume) that generates variable blood pressure (systolic and diastolic pressure). Since the heart in Diastole is longer than in Systole, the formula for calculating average blood pressure or PAM is approximately:PAM (2*P.Diastolic + P.Systolic)/3In situations of tachycardia the cycles of Sist :P AM (P.Diastolic + P.Sistolic)/2A PAM greater than 60 mmHg is assumed to be sufficient to keep the organs of the average person irrigated with blood. If the PAM falls from this value for a considerable time, the organs do not receive sufficient blood supply and become ischemic. Back to the dictionary It is used as average blood pressure at average pressure (it is not simply an arithmetic agent) in the large during the heart cycle. This value is getting closer and closer to diastolic blood pressure. Another definition would be the value of constant blood pressure, which would produce the same flow rate (heart minute volume) with the same peripheral resistance that generates variable blood pressure (systolic and diastolic pressure). [1] Calculation of mean blood pressure can be determined by the following equation:[2] P A M (G C X R V S) + P V C 'displaystyle PAM'(GCXRVS)+PVC', where: PAM: Average blood pressure GC: cardiac effort RVS: Systemic vascular resistance PVC:Central venous pressure, usually negligible. Estimate During rest period, PAM may approach with blood pressure, systolic blood pressure and diastolic blood pressure measurements. [4] P A M - P A D + 1 3 (P A S ? P A D) .displaystyle PAM.simeq PAD+.frac {1}{3}(PAS-PAD) or P A M 2 3 (P A D) + 1 3 (P A S {2}{3}) . . . . . {1} {3} . . . . . simeq 'frac'(2PAD)+PAS'{3}', where PAM: Blood Pressure Average PAS: Systolic Blood Pressure PAD: Diastolic Blood Pressure PP is Pulse Pressure P A S s P A D 'Displaystyle PAS-PAD' In Tachycardia, the calculation is closer to the average of PAS and PAD; since the increase in heart rate shortens the duration of the diastole in the heart cycle, and therefore the duration of diastolic pressures in the circulation is shorter. Clinical relevance PAM is considered to be infusion pressure of body organs. A PAM larger than 60 mmHg is assumed to be sufficient to maintain the organs of the average person. If the PAM falls from this value for a considerable time, the white organ will not receive sufficient blood supply and becomes ischemic. Note that a value between 60-89 mmHg of the diastolic pressure 90-139 mmHg systolic pressure is considered normal.
